ABSTRACT: Background: Malassezia species are dimorphic mycoflora of human skin with colonization as early as the neonatal period. However, they are often associated with superficial skin infection known as pityriasis/tinea versicolor with little reports on their involvement in systemic diseases in developing nations. Recent rise in cases of morbidity and mortality due to fungal sepsis among children in developing countries warrants the present study to determine the occurrence of Malassezia fungemia with cases of pityriasis versicolor (PV) and bacteremia among pupils attending public primary schools in Ogun State, Nigeria.

Materials and Methods: Venous blood samples of 232 pupils with symptoms of PV and those of 67 asymptomatic pupils were cultured in pairs of glucose broth with and without olive oil before subculturing on Sabouraud Dextrose agar, Blood agar and MacConkey agar plates. Skin scrapings of the symptomatic pupils were separately cultured on the three agar plates. The microbial isolates were speciated using cultural, morphological and biochemical methods.

Results: Of the 232 skin scrapings of symptomatic pupils, 166 (71.6%) were found to be cultural positive for Malassezia species in, which M. restricta gave the highest isolation frequency of 71.7% followed by M. globosa (22.9%), M. obtusa (3.6%) and M. slooffiae (1.8%) while the blood cultures of 49 (21.1%) showed occurrence of these respective fungi to be 55.1%, 36.7%, 8.2% and 0.0%. The frequencies of bacteria in the blood cultures of symptomatic pupils were: Pseudomonas spp. 27.5%, Staphylococcus aureus 20.9%, Proteus spp. 18.7%, Klebsiella spp. 14.3%, Enterococcus faecalis 9.9% and Staphylococcus epidermidis 8.8%. Fungemia and bacteremia were found to be significantly associated with symptomatic PV (P< 0.05) when compared with asymptomatic cases. Ten patterns of fungi and bacteria blood co-infections were obtained in the symptomatic PV.

Discussion: The result of this study has shown that symptomatic PV is both a superficial and systemic mycosis and could occur as a co-infection with bacteremia in pupils. These findings should be considered in the management of this common mycotic infection of the skin. [Academia Arena, 2010;2(1):1-5]. (ISSN 1553-992X).

1. Introduction
Pityriasis versicolor is a superficial mycotic infection caused by yeasts of the genus Malassezia, which may also be found on normal human skin (Arzumanian, 2001; Ashbee et al, 2002; Salah et al, 2005; Gaitanis et al, 2006). Some species of Malassezia have complex lipid requirements for growth, which also explains their occurrence on the skin (Thoma et al, 2004). In recent years, rare cases of systemic infections and fungemias caused by Malassezia have been reported (Schmidt, 1997; Ashbee et al, 2002; Thoma et al, 2004). The distribution and ecology of Malassezia species and cutaneous bacteria on human skin has also been reported (Leeming et al, 1989). However, there is paucity of report on systemic co-infections of Malassezia and bacteria especially in developing nations where tropical and subtropical climates, poor hygiene, malnutrition and immunosuppression are very common. All these have been reported as possible predisposing factors to the infections caused by Malassezia species and bacteria (Leeming et al, 1989; Dutta et al, 2002, Gulec et al, 2003). Regarding these probable and possible risk factors, we thought that pupils attending public primary
schools form a unique population affected by these infectious agents. Therefore, we decided to evaluate
some aspects of systemic co-infections between *Malassezia* and bacteria species in them.

2. **Materials and Methods**

2.1 **Sample Collection**

This cross sectional study was conducted in the year 2008 in six public primary schools in Sagamu, a
town in Ogun State in Nigeria with a tropical climate. Two hundred and thirty two male and female pupils with
depigmented skin lesions resembling pityriasis versicolor (PV) were randomly selected among 1048 pupils in the
schools. Also, 67 asymptomatic pupils were randomly selected as controls among the pupils in the schools.
The study protocol was approved by the research committee of Olabisi Onabanjo University Teaching Hospital
(OOUTH) and the parents of the selected pupils gave informed consent before enrollment in the study. Skin
scrapings were obtained from only the pupils with depigmented skin lesions by means of sellotape as
described by Tarazooie et al., 2004, while venous blood samples were aseptically taken from both subjects and
controls. Pupils with skin lesions were treated with To-To ointment and soap products in line with a clinical trial
conducted by Alebiosu et al., (2003).

2.2 **Isolation and Identification**

A portion of the skin scrapings were observed in
wet mount prepared with 10% KOH and methylene blue
direct microscopy and the remaining portion was
cultured on pairs of Sabouraud Dextrose Agar (SDA)
plates with and without olive oil disks. Infection was
assessed by observing morphological features of
Malassezia including budding cells and/or hyphae under
x40 objective lens. Also the rapid and luxuriant growth of
Malassezia in 5 days at 30 – 37° C on SDA plates in the
presence of olive oil disks coupled with the results
obtained from the physiological and biochemical tests
including catalase, urease splitting of esculin and Tween
assimilation were further used in speciating Malassezia
isolates according to methods described by Salah et al
(2005). The venous blood samples were first cultured in
pairs of glucose broth enriched with and without olive oil
at 37°C for 48h to isolate *Malassezia* species and for 7-14
days to isolate bacteria before subculturing on blood agar,
chocolate agar, MacConkey agar and SDA. The bacteria
were then identified by means of cultural, morphological
and biochemical methods as described by Cheesebrough
(1985).

2.3 **Statistical Analysis**

Chi-square ($X^2$) was used as a test of significant
association between PV, malassezia fungemia and
bacteremia at 95% confidence interval. P values equal
or less than 0.05 were considered significant.

3. **Results**

One hundred and sixty six skin scrapings
(71.6%) out of the two hundred and thirty two (232)
pupils with skin lesions resembling PV were found to
be culture positive for *Malassezia* species while 49
(21.2%) were blood culture positive for these yeasts.
The frequency distribution of the yeasts from the skin
lesions showed that *M. restricta* (71.7%) was the most
prevalent followed by *M. globosa* (22.9%) while low
frequencies were recorded for *M. obtusa* (3.6%) and
*M. slooffiae* (1.8%). The blood cultures of 49 (21.2%)
depicted occurrence of these yeasts to be 55.1%, 36.7%, 8.2% and 0.0% respectively (Table 1). Ninety
one (39.2%) of the 166 pupils with skin lesions were
positive for bacteria blood culture with *Pseudomonas*
species having the highest frequency of 27.5%,
followed by *Staphylococcus aureus* 20.9%, *Proteus*
species (17.8%), *Klebsiella* spp (14.3%), *Enterococcus
aeacalis* (9.9%) and *Staphylococcus epidermidis* (8.8%) (Table 2). When the frequencies of malassezia were
compared between symptomatic and asymptomatic PV,
fungemia was found to be significantly associated with
symptomatic PV ($X^2 = 4.56$, $P<0.05$) (Table 3). Similar
comparison of the results of bacteria blood cultures
between the two groups showed that bacteremia was
significantly associated with symptomatic PV ($X^2=20.60$, $P < 0.05$) (Table 4). Seventeen (10.2%)
of the 166 pupils with culture positive skin lesions exhibited ten patterns of *Malassezia* and bacteria
species co-infections in their blood with highest
frequency of 17.6% each for *M. restricta* and *S.aureus,
M.restricta and Proteus* spp, and *M.restricta and
Pseudomonas* spp (Table 5).

4. Discussion

Out of 232 pupils with lesions suggestive of pityriasis versicolor, 166 (71.6 percent) of them were confirmed to be having the disease by positive culture results. Among the primary school pupils with skin lesions recruited in this study, a significant association was found between PV and malassezia fungemia indicating malassezia invasive infection \(X^2=4.56, P<0.05\). This result corroborated an earlier report credited to Devlin (2006), which stated that invasive malassezia infection is usually preceded by skin colonization, and if the situation is not arrested it might lead to disease conditions such as meningitis, vasculitis, dacryocystitis, mastitis, peritonitis and thromboembolic disorders with death consequences.

Contrary to most findings in other places of the world, Malassezia globosa was the leading etiological agent of pityriasis versicolor in Iran (Tarazooie et al, 2004), and Tunisia (Salah et al, 2005), it was uncovered in this study that Malassezia restricta was the most predominant species of Malassezia with occurrences of 71.7% and 55.1% in skin lesions and in the blood of the infected pupils respectively. Malassezia globosa was the second most frequently isolated species among the agents. However, no Malassezia furfur, Malassezia pachydermatis nor Malassezia sympodialis was isolated. Only one of the subjects showed co-infection of Malassezia globosa with Malassezia obtusa. This was in accordance with report by Tarazooie et al (2004), which stated that more than one species of Malassezia can be recovered from one sample.

Malassezia species are part of the human-associated skin flora and are also associated with disease under conditions where their ecology is disturbed and/or under impaired host immunity (Cassadevall, 2006). Since opportunistic fungal infections generally occur after a breach of some aspects of the host defense systems, it is not surprising that mixed infections by multiple pathogens are a common phenomenon. Bacterial flora including Enterobacter species, Pseudomonas aeruginosa and Klebsiella pneumoniae accompanying Candida yeast in clinical specimens has been reported (Hermann et al, 1999). The majority of research on bacterial-fungal interactions has focused on the fungus Candida albicans. Much less is known about the interactions between bacteria and Malassezia.

Bacteremia as observed in this study, has been strongly associated with PV \(P < 0.05\). Response from the questionnaire indicated that some of the affected pupils have taken antibacterials in the past, and since the clinical history of the pupils prior to the study was unknown, it was difficult to predict which of these two clinical conditions (i.e PV and bacteremia) precedes each other; and so one cannot state categorically which

http://www.sciencepub.net/academia  aarenaj@gmail.com
of the conditions predisposes to the other as both cases are likely.

Documented evidence exists that; ≥ 3 episodes of sepsis may increase skin colonization by Malassezia species (Feja et al, 2005; Devlin, 2006). On the other hand downregulation of the immune system by Malassezia due to inhibition of pro-inflammatory cytokines by its lamellar (lipid layer of cell-wall), impairment of phagocytic killing by inhibition of hydrogen peroxide production as a result of azelaic acid production coupled with induction of interleukin -10 (IL-10) which is inhibitory to macrophages as stated by Ashbee and Evans (2002); may encourage dissemination of bacterial skin flora, with resultant cases of systemic infections such as bacteremia and septicemia.

Though, detailed mechanism behind Malassezia-bacterial co-isolation in the blood of the studied subjects with PV in this study is unknown, significant association between PV (skin colonization) and Malassezia fungemia (P < 0.05), coupled with co-isolation of Malassezia with Staphylococcus aureus, Staphylococcus epidemis, Pseudomonas species and enteric (Enterococcus faecalis, Proteus species, Klebsiella species) contaminating bacteria in the blood of the subjects suggested that these bacterial isolates might have gained their entry exogenously via skin surfaces or endogenously through the intestine. Since the microbial skin flora can attach themselves to the sticky lamellar of Malassezia (Ashbee and Evans, 2002), they might gain entry into the blood during malassezial invasion. On the other hand, capillary invasion by enteric bacteria may also assist in the dissemination of Malassezia into the blood streams of the hosts.

There is, therefore, the need to learn about different strategies that bacteria use to interact with fungi and vice-versa in the body of human beings and other animals. From the perspective of the bacterium, Hogan and Kolter (2006) postulated that a fungus could represent a synergistic partner for the degradation of complex substrates, a competitor for scarce nutrients or the producer of lethal antibiotics. Survival of the bacterium can depend on its being able to control these interactions. Thus, it is likely that bacteria have evolved numerous ways to manipulate fungal behavior.

The data obtained in this study emphasize the point that the persistence of Malassezia species with bacteria in the blood of the pupils is determined by both their ability to interact with the hosts and their success in competing or acting synergistically with bacteria. While the effects of mixed fungal-bacterial infections on the host have not been well characterized, one can speculate many ways by which these microbial interactions could impact virulence factor production, host immune responses and/or susceptibility to antibiotic therapy.

The result of this study has revealed Malassezia restricta and Malassezia globosa as the predominant etiological agents of pityriasis versicolor among primary school pupils in Ogun State, Nigeria. It has further established that symptomatic PV is both a superficial and systemic mycosis, which could occur as a co-infection with bacteremia in primary school pupils.

It is recommended that the findings of this study be considered in the management of PV, which is a common mycotic infection of the skin. Future research incorporating molecular study is hereby advocated in this area.

Acknowledgements

We are grateful to the management of Smooford International Ltd, Iperu-Remo, Ogun State, Nigeria for donating To-To ointment and soap used in treating the pupils with lesions resembling PV and also to the management of the primary schools where clinical specimens were collected from the pupils.
